## Abstract

We consider the problem of routing a data packet through the visibility graph of a polygonal domain  $P$  with  $n$  vertices and  $h$  holes. We may preprocess  $P$  to obtain a *label* and a *routing table* for each vertex of  $P$ . Then, we must be able to route a data packet between any two vertices  $p$  and  $q$  of  $P$ , where each step must use only the label of the target node  $q$  and the routing table of the current node.

For any fixed  $\varepsilon > 0$ , we present a routing scheme that always achieves a routing path whose length exceeds the shortest path by a factor of at most  $1 + \varepsilon$ . The labels have  $O(\log n)$  bits, and the routing tables are of size  $O((\varepsilon^{-1} + h) \log n)$ . The preprocessing time is  $O(n^2 \log n)$ . It can be improved to  $O(n^2)$  for simple polygons.

## 1 Introduction

Routing is a crucial problem in distributed graph algorithms [23, 34]. We would like to preprocess a given graph  $G$  in order to support the following task: given a data packet that lies at some *source* node  $p$  of  $G$ , route the packet to a given *target* node  $q$  in  $G$  that is identified by its *label*. We expect three properties from our routing scheme: first, it should be *local*, i.e., in order to determine the next step for the packet, it should use only information stored with the current node of  $G$  or with the packet itself. Second, the routing scheme should be *efficient*, meaning that the packet should not travel much more than the shortest path distance between  $p$  and  $q$ . The ratio between the length of the routing path and the shortest path in the graph is also called *stretch factor*. Third, it should be *compact*: the total space requirement should be as small as possible.

Here is an obvious solution: for each node  $v$  of  $G$ , we store at  $v$  the complete shortest path tree for  $v$ . Thus, given the label of a target node  $q$ , we can send the packet for one more step along the shortest path from  $v$  to  $q$ . Then, the routing scheme will have perfect efficiency, sending each packet along a shortest path. However, this method requires that each node stores its entire shortest path tree, making it not compact. Thus, the challenge lies in finding the right balance between the conflicting goals of compactness and efficiency.

---

37 Thorup and Zwick introduced the notion of a *distance oracle* [42]. Given a graph  $G$ , the goal is to  
 38 construct a compact data structure to quickly answer *distance queries* for any two nodes in  $G$ . A routing  
 39 scheme can be seen as a distributed implementation of a distance oracle [36].

40 The problem of constructing a compact routing scheme for a general graph has been studied for a  
 41 long time [1, 3, 16, 18, 21, 35, 36]. One of the most recent results, by Roditty and Tov, dates from 2016 [36].  
 42 They developed a routing scheme for a general graph  $G$  with  $n$  vertices and  $m$  edges. Their scheme needs  
 43 to store a poly-logarithmic number of bits with the packet, and it routes a message from  $p$  to  $q$  on a  
 44 path with length  $O(k\Delta + m^{1/k})$ , where  $\Delta$  is the shortest path distance between  $p$  and  $q$  and  $k > 2$  is any  
 45 fixed integer. The routing tables use  $mn^{O(1/\sqrt{\log n})}$  total space. In general graphs, any routing scheme  
 46 with constant stretch factor needs to store  $\Omega(n^c)$  bits per node, for some constant  $c > 0$  [34]. Thus, it is  
 47 natural to ask whether there are better algorithms for specialized graph classes. For instance, trees admit  
 48 routing schemes that always follow the shortest path and that store  $O(\log n)$  bits at each node [22, 37, 41].  
 49 Moreover, in planar graphs, for any fixed  $\varepsilon > 0$ , there is a routing scheme with a poly-logarithmic number  
 50 of bits in each routing table that always finds a path that is within a factor of  $1 + \varepsilon$  from optimal [40].  
 51 Similar results are also available for unit disk graphs [26], and for metric spaces with bounded doubling  
 52 dimension [29].

53 Another approach is called *geometric routing*. Here, the graph is embedded in a geometric space, and  
 54 the routing algorithm has to determine the next vertex for the data packet based on the location of the  
 55 source and the target vertex, the current vertex, and its neighbourhood, see for instance [9, 10] and the  
 56 references therein. The most notable difference between geometric routing and our setting is that in  
 57 geometric routing, vertices are generally not allowed to store routing tables, so that routing decisions are  
 58 based solely on the geometric information available at the current vertex (and possibly information stored  
 59 in the message). We note that the location of the source vertex may or may not be needed, depending on  
 60 the routing algorithm. For example, the routing algorithm for triangulations by Bose and Morin [13] uses  
 61 the line segment between the source and the target for its routing decisions. A recent result by Bose *et*  
 62 *al.* [10] is very close to our setting. They show that when vertices do not store any routing tables (i.e.,  
 63 each vertex stores only the edges that can be followed from it), no geometric routing scheme can achieve  
 64 stretch factor  $o(\sqrt{n})$ . This lower bound applies regardless of the amount of information that may be  
 65 stores in the message.

66 Here, we consider the class of visibility graphs of a polygonal domain. Let  $P$  be such a polygonal  
 67 domain with  $h$  holes and  $n$  vertices. Two vertices  $p$  and  $q$  in  $P$  are connected by an edge if and only if they  
 68 can *see* each other, i.e., if and only if the line segment between  $p$  and  $q$  is contained in the (closed) region  
 69  $P$ . We note that this definition implies that the visibility graph contains the shortest path between any  
 70 two vertices of the polygonal domain. The problem of computing a shortest path between two vertices in  
 71 a polygonal domain has been well-studied in computational geometry [2, 4, 24, 25, 27, 28, 30, 31, 33, 38, 39, 43].  
 72 Nevertheless, to the best of our knowledge, prior to our work there have been no routing schemes for  
 73 visibility graphs of polygonal domains that fall into our model.

74 When we relax the requirement on the length of the path, we enter the domain of spanners: given a  
 75 graph  $G$ , a subgraph  $H$  of  $G$  is a  $k$ -*spanner* of  $G$  if for all pairs of vertices  $p$  and  $q$  in  $G$ ,  $d_H(p, q) \leq k \cdot d_G(p, q)$ ,  
 76 for  $k \geq 1$ . The spanning properties of various geometric graphs have been studied extensively in the  
 77 literature (see [15, 32] for a comprehensive overview). We briefly mention the results that are most closely  
 78 related to the approach we will take here, namely Yao-graphs [45] and  $\Theta$ -graphs [17]. Intuitively, these  
 79 graphs form geometric networks where each vertex connects to its nearest visible vertex in a certain  
 80 number of different directions (a formal definition is given in Section 3). Both types of graphs are spanners,  
 81 where the stretch factor depends on the number of cones used [5–8, 14, 19, 20]. These graphs have also  
 82 been considered for geometric routing purposes. For example, Bose *et al.* [9] gave an optimal geometric  
 83 routing algorithm for the half- $\Theta_6$ -graph (the  $\Theta$ -graph with six cones where edges are added in every  
 84 other cone). When considering obstacles,  $\Theta$ -graphs have recently been used to route on (subgraphs of)  
 85 the visibility graph [10–12], though these algorithms do not provide a bound on the total length of the  
 86 routing path, only on the number of edges followed by the routing scheme. However, as mentioned earlier,  
 87 these geometric routing schemes cannot achieve a stretch factor of  $o(\sqrt{n})$ , as they are not allowed to store  
 88 routing tables at the vertices.

89 We introduce a routing scheme that, for any  $\varepsilon > 0$ , needs  $O((1/\varepsilon + h) \log n)$  bits in each routing table,  
90 and for any two vertices  $p$  and  $q$ , it produces a routing path that is within a factor of  $1 + \varepsilon$  of optimal.  
91 This shows that by allowing a routing table at each vertex, we can do much better than in traditional  
92 geometric routing, achieving a stretch factor that is arbitrarily close to 1.

## 93 2 Preliminaries

94 Let  $G = (V, E)$  be an *undirected, connected and simple* graph. In our model,  $G$  is embedded in the  
95 Euclidean plane: a *node*  $p = (p_x, p_y) \in V$  corresponds to a point in the plane, and an edge  $\{p, q\} \in E$  is  
96 represented by the line segment  $\overline{pq}$ . The *length*  $|\overline{pq}|$  of an edge  $\{p, q\}$  is the Euclidean distance between  
97 the points  $p$  and  $q$ . The length of a shortest path between two nodes  $p, q \in V$  is denoted by  $d(p, q)$ .

98 We formally define a *routing scheme* for  $G$ . Each node  $p$  of  $G$  is assigned a *label*  $\ell(p) \in \{0, 1\}^*$  that  
99 identifies it in the network. Furthermore, we store with  $p$  a *routing table*  $\rho(p) \in \{0, 1\}^*$ . The routing  
100 scheme works as follows: the packet contains the label  $\ell(q)$  of the target node  $q$ , and initially it is situated  
101 at the start node  $p$ . In each step of the routing algorithm, the packet resides at a current node  $p' \in V$ . It  
102 may consult the routing table  $\rho(p')$  of  $p'$  and the label  $\ell(q)$  of the target to determine the next node  $q'$  to  
103 which the packet is forwarded. The node  $q'$  must be a neighbor of  $p'$  in  $G$ . This is repeated until the  
104 packet reaches its destination  $q$ . The scheme is modeled by a *routing function*  $f : \rho(V) \times \ell(V) \rightarrow V$ .

105 In the literature, there are varying definitions for the notion of a routing scheme [26, 36, 44]. For  
106 example, we may sometimes store additional information in the *header* of a data packet (it travels with  
107 the packet and can store information from past vertices). Similarly, the routing function sometimes allows  
108 the use of an *intermediate* target label. This is helpful for recursive routing schemes. Here, however, we  
109 will not need any of these additional capabilities.

110 As mentioned, the routing scheme operates by repeatedly applying the routing function. More precisely,  
111 given a start node  $p \in V$  and a target label  $\ell(q)$ , the scheme produces the sequence of nodes  $p_0 = p$  and  
112  $p_i = f(\rho(p_{i-1}), \ell(q))$ , for  $i \geq 1$ . Naturally, we want routing schemes for which every packet reaches its  
113 desired destination. More precisely, a routing scheme is *correct* if for any  $p, q \in V$ , there exists a finite  
114  $k = k(p, q) \geq 0$  such that  $p_k = q$  (and  $p_i \neq q$  for  $0 \leq i < k$ ). We call  $p_0, p_1, \dots, p_k$  the *routing path*  
115 between  $p$  and  $q$ . The *routing distance* between  $p$  and  $q$  is defined as  $d_\rho(p, q) = \sum_{i=1}^k |\overline{p_{i-1}p_i}|$ .

116 The quality of the routing scheme is measured by several parameters:

- 117 1. the *label size*  $\max_{p \in V} |\ell(p)|$ ,
- 118 2. the *table size*  $\max_{p \in V} |\rho(p)|$ ,
- 119 3. the *stretch factor*  $\max_{p \neq q \in V} d_\rho(p, q)/d(p, q)$ , and
- 120 4. the preprocessing time.

121 Let  $P$  be a polygonal domain with  $n$  vertices. The *boundary*  $\partial P$  of  $P$  consists of  $h$  pairwise disjoint  
122 simple closed polygonal chains: one *outer boundary* and  $h - 1$  *hole boundaries*, or  $h$  *hole boundaries* with  
123 no outer boundary. All hole boundaries lie inside the outer boundary, and no hole boundary lies inside  
124 another hole boundary. In both cases, we say that  $P$  has  $h$  holes. The interior induced by any hole  
125 boundary and the exterior of the outer boundary are not contained in  $P$ . We denote the (open) *interior*  
126 of  $P$  by  $\text{int } P$ , i.e.,  $\text{int } P = P \setminus \partial P$ . We assume that  $P$  is in general position: no three vertices of  $P$  lie  
127 on a common line, and for each pair of vertices in  $P$ , the shortest path between them is unique. Let  $n_i$ ,  
128  $0 \leq i \leq h - 1$ , be the number of vertices on the  $i$ -th boundary of  $P$ . For each boundary  $i$ , we number the  
129 vertices from 0 to  $n_i - 1$ , in clockwise order if  $i$  is a hole boundary, or in counterclockwise order if  $i$  is the  
130 outer boundary. The  $k$ th vertex of the  $i$ th boundary is denoted by  $p_{i,k}$ .

131 Two points  $p$  and  $q$  in  $P$  can *see each other* in  $P$  if and only if  $\overline{pq} \subset P$ . By our general position  
132 assumption,  $\overline{pq}$  touches  $\partial P$  only if  $\overline{pq}$  is itself an edge of  $P$ . The *visibility graph* of  $P$ ,  $\text{VG}(P)$ , has the  
133 same vertices as  $P$  and an edge between two vertices if and only if they see each other in  $P$ . We show the  
134 following main theorem:

135 **Theorem 2.1.** Let  $P$  be a polygonal domain with  $n$  vertices and  $h$  holes. For any  $\varepsilon > 0$ , we can construct  
 136 a routing scheme for  $\text{VG}(P)$  with labels of  $O(\log n)$  bits and routing tables of  $O((1/\varepsilon + h) \log n)$  bits per  
 137 vertex. For any two sites  $p, q \in P$ , the scheme produces a routing path with stretch factor at most  $1 + \varepsilon$ .  
 138 The preprocessing time is  $O(n^2 \log n)$ . If  $P$  is a simple polygon, the preprocessing time reduces to  $O(n^2)$ .

### 139 3 Cones in Polygonal Domains

140 Let  $P$  be a polygonal domain with  $n$  vertices and  $h$  holes. Furthermore, let  $t \geq 3$  be an integer parameter,  
 141 to be determined later. Following Yao [45] and Clarkson [17], we subdivide the visibility polygon of each  
 142 vertex in  $P$  into  $t$  cones with a small enough apex angle. This will allow us to construct compact routing  
 143 tables that support a routing algorithm with small stretch factor.

Figure 1: The cones and rays of a vertex  $p$  with apex angle  $\alpha$ .

144 Let  $p$  be a vertex in  $P$  and  $p'$  the clockwise neighbor of  $p$  if  $p$  is on the outer boundary, or the  
 145 counterclockwise neighbor of  $p$  if  $p$  lies on a hole boundary. We denote with  $\mathbf{r}(p)$  the ray from  $p$  through  
 146  $p'$ . To obtain our cones, we rotate  $\mathbf{r}(p)$  by certain angles. Let  $\alpha$  be the inner angle at  $p$ . For  $j = 0, \dots, t$ ,  
 147 we write  $r_j(p)$  for the ray  $\mathbf{r}(p)$  rotated clockwise by angle  $j \cdot \alpha/t$ .

148 Now, for  $j = 1, \dots, t$ , the cone  $C_j(p)$  has apex  $p$ , boundary  $r_{j-1}(p) \cup r_j(p)$ , and opening angle  $\alpha/t$ ;  
 149 see Figure 1. For technical reasons, we define  $r_j(p)$  not to be part of  $C_j(p)$ , for  $1 \leq j < t$ , whereas we  
 150 consider  $r_t(p)$  to be part of  $C_t(p)$ . Furthermore, we write  $\mathcal{C}(p) = \{C_j(p) \mid 1 \leq j \leq t\}$  for the set of all  
 151 cones with apex  $p$ . Since the opening angle of each cone is  $\alpha/t \leq 2\pi/t$  and since  $t \geq 3$ , each cone is  
 152 convex.

153 The following proof is similar to the one given by Clarkson [17] and Narasimhan and Smid [32], though  
 154 the former shows only that the construction leads to an  $O(1/\varepsilon)$ -spanner instead of showing a more precise  
 155 bound in terms of the number of cones.

156 **Lemma 3.1.** Let  $p$  be a vertex of  $P$  and let  $\{p, q\}$  be an edge of  $\text{VG}(P)$  that lies in the cone  $C_j(p)$ .  
 157 Furthermore, let  $s$  be a vertex of  $P$  that lies in  $C_j(p)$ , is visible from  $p$ , and that is closest to  $p$ . Then,  
 158  $d(s, q) \leq |\overline{pq}| - (1 - 2 \sin(\pi/t)) |\overline{ps}|$ .

159 *Proof.* Let  $s'$  be the point on the line segment  $\overline{pq}$  with  $|\overline{ps'}| = |\overline{ps}|$ ; see Figure 2. Since  $p$  can see  $q$ , we  
 160 have that  $p$  can see  $s'$  and  $s'$  can see  $q$ . Furthermore,  $s$  can see  $s'$ , because  $p$  can see  $s$  and  $s'$  and we  
 161 chose  $s$  to be closest to  $p$ , so the triangle  $\Delta(p, s, s')$  cannot contain any vertices or (parts of) edges of  $P$   
 162 in its interior. Now, the triangle inequality yields  $d(s, q) \leq |\overline{ss'}| + |\overline{s'q}|$ . Let  $\beta$  be the inner angle at  $p$

Figure 2: Illustration of Lemma 3.1. The points  $s$  and  $s'$  have the same distance to  $p$ . The dashed line represents the shortest path from  $s$  to  $q$ .

163 between the line segments  $\overline{ps}$  and  $\overline{ps'}$ . Since both segments lie in the cone  $C_j(p)$ , we get  $\beta \leq 2\pi/t$ . Thus,  
 164 the angle between  $\overline{s'p}$  and  $\overline{s'q}$  is  $\gamma = \pi/2 - \beta/2$ . Using the sine law and  $\sin 2x = 2 \sin x \cos x$ , we get

$$165 \quad |\overline{ss'}| = |\overline{ps}| \cdot \frac{\sin \beta}{\sin \gamma} = |\overline{ps}| \cdot \frac{\sin \beta}{\sin((\pi/2) - (\beta/2))} = |\overline{ps}| \cdot \frac{2 \sin(\beta/2) \cos(\beta/2)}{\cos(\beta/2)} \leq 2|\overline{ps}| \sin(\pi/t).$$

166 Furthermore, we have  $|\overline{s'q}| = |\overline{pq}| - |\overline{ps'}| = |\overline{pq}| - |\overline{ps}|$ . Thus, the triangle inequality gives

$$167 \quad d(s, q) \leq 2|\overline{ps}| \sin(\pi/t) + |\overline{pq}| - |\overline{ps}| = |\overline{pq}| - (1 - 2 \sin(\pi/t)) |\overline{ps}|,$$

168 as claimed. □

## 169 4 The Routing Scheme

170 Let  $\varepsilon > 0$ , and let  $P$  be a polygonal domain with  $n$  vertices and  $h$  holes. We describe a routing scheme  
 171 for  $\text{VG}(P)$  with stretch factor  $1 + \varepsilon$ . The idea is to compute for each vertex  $p$  the corresponding set of  
 172 cones  $\mathcal{C}(p)$  and to store a certain interval of indices for each cone  $C_j(p)$  in the routing table of  $p$ . If an  
 173 interval of a cone  $C_j(p)$  contains the target vertex  $t$ , we proceed to the nearest neighbor of  $p$  in  $C_j(p)$ ; see  
 174 Figure 3. We will see that this results in a routing path with small stretch factor.

Figure 3: The idea of the routing scheme. The first edge on a shortest path from  $p$  to  $q$  (red) is contained in  $C_j(p)$ . The routing algorithm will route the packet from  $p$  to  $s$  (green), the closest vertex to  $p$  in  $C_j$ .

175 In the preprocessing phase, we first compute the label of each vertex  $p_{i,k}$ . The label of  $p_{i,k}$  is the  
 176 binary representation of  $i$ , concatenated with the binary representation of  $k$ . Thus, all labels are distinct  
 177 binary strings of length  $\lceil \log h \rceil + \lceil \log n \rceil$ .

178 Let  $p$  be a vertex in  $P$ . Throughout this section, we will write  $\mathcal{C}$  and  $C_j$  instead of  $\mathcal{C}(p)$  and  $C_j(p)$ .  
 179 The routing table of  $p$  is constructed as follows: first, we compute a shortest path tree  $T$  for  $p$ . For

180 a vertex  $s$  of  $P$ , let  $T_s$  be the subtree of  $T$  with root  $s$ , and denote the set of all vertices on the  $i$ -th  
 181 hole in  $T_s$  by  $I_s(i)$ . The following well-known observation lies at the heart of our routing scheme. For  
 182 completeness, we include a proof.

183 **Observation 4.1.** *Let  $q_1$  and  $q_2$  be two vertices of  $P$ . Let  $\pi_1$  be the shortest path in  $T$  from  $p$  to  $q_1$ , and  
 184  $\pi_2$  the shortest path in  $T$  from  $p$  to  $q_2$ . Let  $l$  be the lowest common ancestor of  $q_1$  and  $q_2$  in  $T$ . Then,  $\pi_1$   
 185 and  $\pi_2$  do not cross or touch in a point  $x$  with  $d(p, x) > d(p, l)$ .*

186 *Proof.* Suppose first that  $\pi_1$  touches  $\pi_2$  in a point  $x$  with  $d(p, x) > d(p, l)$ . The edges of  $T$  are line  
 187 segments, so this can only happen if  $x$  is a vertex. But then  $T$  would contain a cycle, which is impossible.

188 Next, suppose that  $\pi_1$  and  $\pi_2$  cross in a point  $x$  with  $d(p, x) > d(p, l)$ . Suppose further that  $x$  lies on  
 189 the edge  $e_1 = (s_1, t_1)$  of  $\pi_1$  and the edge  $e_2 = (s_2, t_2)$  of  $\pi_2$ ; see Figure 4. Without loss of generality, we  
 190 have  $d(l, s_1) + |\overline{s_1x}| \leq d(l, s_2) + |\overline{s_2x}|$ . Since  $x \in \text{int } P$ , there is a  $\delta > 0$  such that the disk  $D$  with center  $x$   
 191 and radius  $\delta$  is contained in  $P$ . Now consider the intersection  $y_1$  of  $\partial D$  with  $\overline{s_1x}$  and the intersection  $y_2$   
 192 of  $\partial D$  with  $\overline{x t_2}$ . We have  $\overline{y_1 y_2} \subset D \subset P$ , and the triangle inequality yields  $|\overline{y_1 x}| + |\overline{x y_2}| > |\overline{y_1 y_2}|$ . Hence,  
 193 the path  $s_1 y_1 y_2 t_2$  is a shortcut from  $l$  to  $t_2$ , a contradiction to  $\pi_2$  being a shortest path.  $\square$

Figure 4: Two shortest paths that originate in  $p$  cannot cross.

Figure 5: The shortest path from  $p$  to  $a$  (green) crosses the shortest path from  $p$  to  $q_1$  (red). This gives a contradiction by Observation 4.1.

194 **Lemma 4.2.** *Let  $e = (p, s)$  be an edge in  $T$ . Then, the indices of the vertices in  $I_s(i)$  form an interval.  
 195 Furthermore, let  $f = (p, s')$  be another edge in  $T$ , such that  $e$  and  $f$  are consecutive edges in  $T$  around  
 196  $p$ .<sup>1</sup> Then, the indices of the vertices in  $I_s(i) \cup I_{s'}(i)$  are again an interval.*

<sup>1</sup>By this, we mean that there is no other edge of  $T$  incident to  $p$  in the cone that is spanned by  $e$  and  $f$  and that extends into the interior of  $P$ .

197 *Proof.* For the first part of the lemma, suppose that the indices for  $I_s(i)$  do not form an interval. Then,  
198 there are two vertices  $q_1, q_2 \in I_s(i)$  such that if we consider the two polygonal chains  $H_1$  and  $H_2$  with  
199 endpoints  $q_1$  and  $q_2$  that constitute the boundary of hole  $i$ , there are two vertices  $a, b \notin I_s(i)$  with  $a \in H_1$   
200 and  $b \in H_2$  (see Figure 5). Let  $\pi_1$  and  $\pi_2$  be the shortest paths in  $T$  from  $s$  to  $q_1$  and from  $s$  to  $q_2$ . Let  $r$   
201 be the last common vertex of  $\pi_1$  and  $\pi_2$ , and let  $\tilde{\pi}_1$  be the subpath of  $\pi_1$  from  $r$  to  $q_1$  and  $\tilde{\pi}_2$  the subpath  
202 of  $\pi_2$  from  $r$  to  $q_2$ . Consider the set  $\mathcal{D}$  of (open) connected components of  $P \setminus (\tilde{\pi}_1 \cup \tilde{\pi}_2)$ . Any vertex of  $P$   
203 that is on the boundary of two different components of  $\mathcal{D}$  must lie on  $\tilde{\pi}_1 \cup \tilde{\pi}_2$ . Hence,  $p$ ,  $a$ , and,  $b$  each lie  
204 on the boundary of exactly one component in  $\mathcal{D}$ , and the components  $D_a$  and  $D_b$  with  $a$  and  $b$  on the  
205 boundary are distinct. Suppose without loss of generality that  $p \notin \partial D_a$ . Then, there has to be a child  $\tilde{s}$   
206 of  $p$  in  $T$  such that  $a \in I_{\tilde{s}}(i)$  and such that the shortest path from  $\tilde{s}$  to  $a$  crosses  $\pi_1 \cup \pi_2$ . Since  $p$  is the  
207 lowest common ancestor of  $a$  and  $q_1$  and of  $a$  and  $q_2$ , this contradicts Observation 4.1.

208 The proof for the second part is very similar. We assume for the sake of contradiction that the indices  
209 in  $I_s(i) \cup I_{s'}(i)$  do not form an interval, and we find vertices  $q_1, q_2 \in I_s(i) \cup I_{s'}(i)$  such that if we split the  
210 boundary of hole  $i$  into two chains  $H_1$  and  $H_2$  between  $q_1$  and  $q_2$ , there are two vertices  $a, b \notin I_s(i) \cup I_{s'}(i)$   
211 with  $a \in H_1$  and  $b \in H_2$ . Furthermore, we may assume that  $a \neq p$  and  $b \neq p$ , because otherwise  $q_1$  and  
212  $q_2$  would be the two vertices of  $P$  that share an edge with  $p$ , and thus  $q_1$  and  $q_2$  would be the only two  
213 children of  $p$  in  $T$  and  $I_s(i) \cup I_{s'}(i)$  would be an interval. Let  $\pi_1$  be the shortest path in  $T$  from  $s$  to  $q_1$   
214 and  $\pi_2$  the shortest path in  $T$  from  $s'$  to  $q_2$ , and consider the lowest common ancestor  $r$  of  $q_1$  and  $q_2$  in  
215  $T$  (now  $r$  might be  $p$ ). Let  $\tilde{\pi}_1$  be the subpath of  $\pi_1$  from  $r$  to  $q_1$  and  $\tilde{\pi}_2$  the subpath of  $\pi_2$  from  $r$  to  $q_2$ .  
216 Consider the set  $\mathcal{D}$  of (open) connected components of  $P \setminus (\tilde{\pi}_1 \cup \tilde{\pi}_2)$ . As before, any vertex that lies on  
217 the boundaries of two distinct components of  $\mathcal{D}$  must belong to  $\tilde{\pi}_1 \cup \tilde{\pi}_2$ , so  $a$  and  $b$  are on the boundaries  
218 of two uniquely defined distinct components in  $\mathcal{D}$ . We call these components  $D_a$  and  $D_b$ . Now,  $s$  and  $s'$   
219 are consecutive around  $p$ , so at least one of  $D_a$  and  $D_b$  contains no other child of  $p$  in  $T$  on its boundary.  
220 Let it be  $D_a$ . Then, the shortest path from  $p$  to  $a$  must cross  $\pi_1 \cup \pi_2$ , contradicting Observation 4.1.  $\square$

221 Lemma 4.2 indicates how to construct the routing table  $\rho(p)$  for  $p$ . We set

$$222 \quad t = \left\lceil \pi / \arcsin \left( \frac{1}{2(1+1/\varepsilon)} \right) \right\rceil, \quad (1)$$

223 and we construct a set  $\mathcal{C}$  of cones for  $p$  as in Section 3. Let  $C_j \in \mathcal{C}$  be a cone, and let  $\Pi_i$  be a hole  
224 boundary or the outer boundary. We define  $C_j \cap \Pi_i$  as the set of all vertices  $q$  on  $\Pi_i$  for which the first  
225 edge of the shortest path from  $p$  to  $q$  lies in  $C_j$ . By Lemma 4.2, the indices of the vertices in  $C_j \cap \Pi_i$   
226 form a (possibly empty) cyclic interval  $[k_1, k_2]$ . If  $C_j \cap \Pi_i = \emptyset$ , we do nothing. Otherwise, if  $C_j \cap \Pi_i \neq \emptyset$ ,  
227 there is a vertex  $r \in C_j$  closest to  $p$ , and we add the entry  $(i, k_1, k_2, \ell(r))$  to  $\rho(p)$ . This entry needs  
228  $2 \cdot \lceil \log h \rceil + 3 \cdot \lceil \log n \rceil$  bits.

229 Now, the routing function  $f : \rho(V) \times \ell(V) \rightarrow V$  is quite simple. Given the routing table  $\rho(p)$  for  
230 the current vertex  $p$  and a target label  $\ell(q) = (i, k)$ , indicating vertex  $k$  on hole  $i$ , we search  $\rho(p)$  for an  
231 entry  $(i, k_1, k_2, \ell(r))$  with  $k \in [k_1, k_2]$ . By construction, this entry is unique. We return  $r$  as the next  
232 destination for the packet (see Figure 3).

## 233 5 Analysis

234 We analyze the stretch factor of our routing scheme and give upper bounds on the size of the routing  
235 tables and the preprocessing time. Let  $\varepsilon > 0$  be fixed, and let  $1 + \varepsilon$  be the desired stretch factor. We set  
236  $t$  as in (1). First, we bound  $t$  in terms of  $\varepsilon$ . This immediately gives  $|\mathcal{C}(p)| \in O(1/\varepsilon)$ , for every vertex  $p$ .

237 **Lemma 5.1.** *We have  $t \leq 2\pi(1 + 1/\varepsilon) + 1$ .*

238 *Proof.* For  $x \in (0, 1/2]$ , we have  $\sin x \leq x$ , so for  $z \in [2, \infty)$ , we get that  $\sin(1/z) \leq 1/z$ . Applying  
239  $\arcsin(\cdot)$  on both sides, this gives  $1/z \leq \arcsin(1/z) \Leftrightarrow 1/\arcsin(1/z) \leq z$ . We set  $z = 2(1 + 1/\varepsilon)$  and  
240 multiply by  $\pi$  to derive the desired inequality.  $\square$

## 241 5.1 The Routing Table

242 Let  $p$  be a vertex of  $P$ . We again write  $\mathcal{C}$  for  $\mathcal{C}(p)$  and  $C_j$  instead of  $C_j(p)$ . To bound the size of  $\rho(p)$ , we  
 243 need some properties of holes with respect to cones. For  $i = 0, \dots, h-1$ , we write  $m(i)$  for the number of  
 244 cones  $C_j \in \mathcal{C}$  with  $C_j \cap \Pi_i \neq \emptyset$ . Then,  $\rho(p)$  contains at most  $|\rho(p)| \leq O\left(\sum_{i=0}^{h-1} m(i) \log n\right)$  bits. We say  
 245 that  $\Pi_i$  is *stretched for the cone*  $C_j$  if there are indices  $0 \leq j_1 < j < j_2 < t$  such that  $C_{j_1} \cap \Pi_i$ ,  $C_j \cap \Pi_i$   
 246 and  $C_{j_2} \cap \Pi_i$  are non-empty. If  $\Pi_i$  is not stretched for any cone of  $p$ , then  $m(i) \leq 2$ . We prove the  
 247 following lemma:

248 **Lemma 5.2.** *For every cone  $C_j \in \mathcal{C}$ , there is at most one boundary  $\Pi_i$  that is stretched for  $C_j$ .*

249 *Proof.* Let  $\Pi_i$  be a hole boundary that is stretched for  $C_j$ . There are indices  $j_1 < j < j_2$  and vertices  
 250  $q \in C_{j_1} \cap \Pi_i$ ,  $r \in C_j \cap \Pi_i$ , and  $s \in C_{j_2} \cap \Pi_i$ . We subdivide  $P$  into three regions  $Q$ ,  $R$  and  $S$ : the boundary  
 251 of  $Q$  is given by the shortest path from  $p$  to  $r$ , the shortest path from  $p$  to  $q$ , and the part of  $\Pi_i$  from  $r$   
 252 to  $q$  not containing  $s$ . Similarly, the region  $R$  is bounded by the shortest path from  $p$  to  $r$ , the shortest  
 253 path from  $p$  to  $s$  and the part of  $\Pi_i$  between  $r$  and  $s$  that does not contain  $q$ . Finally,  $S$  is the closure of  
 254  $P \setminus (Q \cup R)$ . The interiors of  $Q$ ,  $R$ , and  $S$  are pairwise disjoint; see Figure 6.

Figure 6: The shortest paths from  $p$  to  $q$ ,  $r$ ,  $s$  (blue). The hole  $\Pi$  contains  $t$  and lies in  $Q$ .

255 Suppose there is another boundary  $\Pi$  that is stretched for  $C_j$ . Then,  $\Pi$  must lie entirely in either  $Q$ ,  
 256  $R$ , or  $S$ . We discuss the first case, the other two are symmetric. Since  $\Pi$  is stretched for  $C_j$ , there is  
 257 an index  $j' > j$  and a vertex  $t \in C_{j'} \cap \Pi$ . Consider the shortest path  $\pi$  from  $p$  to  $t$ . Since  $j' > j$ , the  
 258 first edge of  $\pi$  lies in  $R$  or  $S$ , and  $\pi$  has to cross or touch the shortest path from  $p$  to  $q$  or from  $p$  to  
 259  $r$ . Furthermore, by definition, we have  $C_j \cap C_{j'} = \{p\}$  and  $C_{j_1} \cap C_{j'} = \{p\}$ . Therefore,  $p$  is the lowest  
 260 common ancestor of all three shortest paths, and Observation 4.1 leads to a contradiction.  $\square$

261 For  $i = 0, \dots, h-1$ , let  $s(i)$  be the number of cones in  $\mathcal{C}$  for which  $\Pi_i$  is stretched. By Lemma 5.2, we  
 262 get  $\sum_{i=0}^{h-1} s(i) \leq |\mathcal{C}(p)| \in O(1/\varepsilon)$ . Since  $m(i) \leq s(i) + 2$ , we conclude

$$263 \quad |\rho(p)| \in O\left(\sum_{i=0}^{h-1} m(i) \log n\right) = O\left(\sum_{i=0}^{h-1} (s(i) + 2) \log n\right) = O((|\mathcal{C}(p)| + 2h) \log n) = O((1/\varepsilon + h) \log n).$$

## 264 5.2 The Stretch Factor

265 Next, we bound the stretch factor. First, we prove that the distance to the target decreases after the first  
 266 step. This will then give the bound on the overall stretch factor.

267 **Lemma 5.3.** *Let  $p$  and  $q$  be two vertices in  $P$ . Let  $s$  be the next vertex computed by the routing scheme  
 268 for a data packet from  $p$  to  $q$ . Then,  $d(s, q) \leq d(p, q) - |\overline{ps}|/(1 + \varepsilon)$ .*

*Proof.* By construction of  $\rho(p)$ , we know that the next vertex  $q'$  on the shortest path from  $p$  to  $q$  lies in  
 the same cone as  $s$ . Hence, by the triangle inequality and Lemma 3.1, we obtain

$$\begin{aligned} d(s, q) &\leq d(s, q') + d(q', q) \leq |\overline{pq'}| - (1 - 2 \sin(\pi/t)) |\overline{ps}| + d(q', q) \\ &= d(p, q) - (1 - 2 \sin(\pi/t)) |\overline{ps}| \leq d(p, q) - \left(1 - \frac{1}{1 + 1/\varepsilon}\right) |\overline{ps}| \quad (\text{definition of } t) \\ &= d(p, q) - |\overline{ps}|/(1 + \varepsilon), \end{aligned}$$

269 as desired.  $\square$

270 Lemma 5.3 immediately shows the correctness of the routing scheme: the distance to the target  $q$   
 271 decreases strictly in each step and there is a finite number of vertices, so there is a  $k = k(p, q) \leq n$  so that  
 272 after  $k$  steps, the packet reaches  $q$ . Using this, we can now bound the stretch factor of the routing scheme.

273 **Lemma 5.4.** *Let  $p$  and  $q$  be two vertices of  $P$ . Then,  $d_\rho(p, q) \leq (1 + \varepsilon)d(p, q)$ .*

274 *Proof.* Let  $\pi = p_0 p_1 \dots p_k$  be the routing path from  $p = p_0$  to  $q = p_k$ . By Lemma 5.3, we have  
 275  $d(p_{i+1}, q) \leq d(p_i, q) - |\overline{p_i p_{i+1}}|/(1 + \varepsilon)$ . Thus,

$$276 \quad d_\rho(p, q) = \sum_{i=0}^{k-1} |\overline{p_i p_{i+1}}| \leq (1 + \varepsilon) \sum_{i=0}^{k-1} (d(p_i, q) - d(p_{i+1}, q)) = (1 + \varepsilon) (d(p_0, q) - d(p_k, q)) = (1 + \varepsilon)d(p, q),$$

277 as claimed.  $\square$

### 278 5.3 The Preprocessing Time

279 Finally, we discuss the details of the preprocessing algorithm and its time complexity.

280 **Lemma 5.5.** *The preprocessing time for our routing scheme is  $O(n^2 \log n + n/\varepsilon)$  for polygonal domains  
 281 and  $O(n^2 + n/\varepsilon)$  for simple polygons.*

282 *Proof.* Let  $p$  be a vertex of  $P$ . We compute the shortest path tree  $T$  for  $p$ . In polygonal domains, this  
 283 takes  $O(n \log n)$  time using the algorithm of Hershberger and Suri [25], and in simple polygons, this needs  
 284  $O(n)$  time, using the algorithm of Guibas *et al.* [24]. We perform a circular sweep around  $p$  to find for  
 285 each cone  $C_j \in \mathcal{C}$  the set  $X_j$  of the children of  $p$  in  $T$  that lie in  $C_j$ . This requires  $O(n + 1/\varepsilon)$  steps.

286 For each cone  $C_j$ , we find the child  $r \in X_j$  that is closest to  $p$ . We traverse all subtrees of  $T$  that are  
 287 rooted at some child in  $X_j$ , and we collect the set  $V_j$  of all their vertices. We group the vertices in  $V_j$   
 288 according to the hole boundaries they belong to. This takes  $O(|V_j|)$  time, using the following *bucketing*  
 289 *scheme*: once for the whole algorithm, we set up an array  $B$  of buckets with  $h$  entries, one for each hole  
 290 boundary. Each bucket consists of a linked list, initially empty. This gives a one-time initialization cost  
 291 of  $O(h)$ . When processing the vertices of  $V_j$ , we create a linked list  $N$  of *non-empty* buckets, also initially  
 292 empty. For each  $v \in V_j$ , we add  $v$  into its corresponding bucket  $B[i]$ . If  $v$  is the first vertex in  $B[i]$ , we  
 293 add  $i$  to  $N$ . This takes  $O(|V_j|)$  time in total, and it leads to the desired grouping of  $V_j$ . Once we have  
 294 processed  $V_j$ , we use  $N$  in order to reset all the buckets we used to empty, in another  $O(|V_j|)$  steps.

295 Now, for each hole  $i$ , let  $V_{j,i}$  be the set of all vertices on  $\Pi_i$  that lie in  $V_j$ . By Lemma 4.2,  $V_{j,i}$  is a  
 296 cyclic interval. To determine its endpoints, it suffices to identify one vertex on hole  $i$  that is not in  $V_{j,i}$  (if  
 297 it exists). After that, a simple scan over  $V_{j,i}$  gives the desired interval endpoints in  $O(|V_{j,i}|)$  additional  
 298 time. To find this vertex in  $O(|V_{j,i}|)$  time, we use prune and search: let  $L = \{p_{i,k} \in V_{j,i} \mid k < \lceil n_i/2 \rceil\}$   
 299 and  $R = V_{j,i} \setminus L$ . We determine  $|L|$  and  $|R|$  by scanning  $V_{j,i}$ , and we distinguish three cases. First, if  
 300  $|L| = \lceil n_i/2 \rceil$  and  $|R| = \lfloor n_i/2 \rfloor$ , all vertices of hole  $i$  lie in the  $V_j$ , and we are done. Second, if  $|L| < \lceil n_i/2 \rceil$   
 301 and  $|R| < \lfloor n_i/2 \rfloor$ , then at least one of  $p_{i,0}$ ,  $p_{i,\lceil n_i/2 \rceil - 1}$ ,  $p_{i,\lceil n_i/2 \rceil}$ , and  $p_{i,n_i - 1}$  is not in  $V_{j,i}$ . Another scan  
 302 over  $V_{j,i}$  reveals which one it is. In the third case, exactly one of the two sets  $L$ ,  $R$  contains all possible  
 303 vertices, whereas the other one does not. We recurse on the latter set. This set contains at most  $|V_{j,i}|/2$   
 304 elements, so the overall running time for the recursion is  $O(|V_{j,i}|)$ .

305 It follows that we can handle a single cone  $C_j$  in time  $O(|V_j|)$ , so the total time for processing  $p$  is  
 306  $O(n \log n + 1/\varepsilon)$  in polygonal domains and  $O(n + 1/\varepsilon)$  in simple polygons. Since we repeat for each vertex  
 307 of  $P$ , the claim follows.  $\square$

308 Combining the last two lemmas with Section 4, we get our main theorem.

309 **Theorem 2.1.** *Let  $P$  be a polygonal domain with  $n$  vertices and  $h$  holes. For any  $\varepsilon > 0$  we can construct  
 310 a routing scheme for  $\text{VG}(P)$  with labels of  $O(\log n)$  bits and routing tables of  $O((1/\varepsilon + h) \log n)$  bits per  
 311 vertex. For any two sites  $p, q \in P$ , the scheme produces a routing path with stretch factor at most  $1 + \varepsilon$ .  
 312 The preprocessing time is  $O(n^2 \log n)$ . If  $P$  is a simple polygon, the preprocessing time reduces to  $O(n^2)$ .*

313 *Proof.* First, note that we may assume that  $\varepsilon = \Omega(1/n)$ , otherwise, the theorem follows trivially from  
 314 storing a complete shortest path tree in each routing table. Thus,  $1/\varepsilon = O(n)$ , and by Lemma 5.5, the  
 315 preprocessing time is  $O(n^2 \log n)$  for polygonal domains, and  $O(n^2)$  for simple polygons. The claim on  
 316 the label size follows from the discussion at the beginning of Section 4, the size of the routing tables is  
 317 given in Section 5.1, and the stretch factor is proved in Lemma 5.4.  $\square$

## 318 6 Conclusion

319 We gave an efficient routing scheme for the visibility graph of a polygonal domain. Our scheme produces  
 320 routing paths whose length can be made arbitrarily close to the optimum.

321 Several open questions remain. First of all, we would like to obtain an efficient routing scheme for the  
 322 *hop-distance* in polygonal domains  $P$ , where each edge of  $\text{VG}(P)$  has unit weight. This scenario occurs  
 323 for routing in a wireless network: here, the main overhead is caused by forwarding a packet at a base  
 324 station, whereas the distance that the packet has to cross is negligible for the travel time. For our routing  
 325 scheme, we can construct examples where the stretch factor is  $\Omega(n)$ ; see Figure 7. Moreover, it would be  
 326 interesting to improve the preprocessing time or the size of the routing tables, perhaps using a recursive  
 strategy.

Figure 7: In this polygon,  $p$  and  $q$  can see each other, so their hop-distance is 1. Our routing scheme routes from one spire to the next, giving stretch factor  $\Theta(n)$ .

327 A final open question concerns routing schemes in general: how do we model the time needed by a  
 328 data packet to travel through the graph, including the processing times at the vertices? In particular, it  
 329 would be interesting to consider a model in which each vertex has a fixed *processing time* until it knows  
 330 the next vertex for the current packet. This would lead to a slightly different, but important, measure for  
 331 routing schemes.  
 332
